A METHOD OF MEASURING THE RESISTIVITY AND HALL COEFFICIENT ON LAMELLAE OF ARBITRARY SHAPE

Resistivity and Hall-coefficient measurements at different temperatures play an important part in research on semiconductors, such as germanium and silicon \(^1\), for it is from these quantities that the mobility and concentration of the charge carriers are found.

Such measurements are commonly carried out with a test bar as illustrated in fig. 1. The resistivity is found directly from the potential difference and the distance between the contacts \(O\) and \(P\), the current \(i\) and the dimensions of the bar. To determine the Hall coefficient the bar is subjected to a magnetic field \(B\) applied at right angles to the direction of the current and to the line connecting the diametrically opposite contacts \(O\) and \(Q\). From the potential difference thus produced between these latter contacts the Hall coefficient is derived. (The relation between the Hall coefficient and the change in electric potential distribution due to a magnetic field will be explained presently.)

![Fig. 1. Classical form of sample used for resistivity and Hall-coefficient measurements. The test bar is provided with current contacts \(M\) and \(N\) and voltage contacts \(O\), \(P\), \(Q\) and \(R\). The fourth voltage contact \(R\) serves for check measurements.](image)

In measurements performed at low temperatures — e.g. in liquid nitrogen — point contacts possess resistances of the order of megohms, in consequence of which the voltages cannot be determined with sufficient accuracy. In such cases "bridge-shaped" samples are used as illustrated in fig. 2. The voltage and current contacts here have a relatively large surface area, and hence the contact resistances are low.

The methods referred to are based on the fact that the geometry of the sample ensures a simple pattern of virtually parallel current stream-lines. Formulae have been devised to correct for the deviation from parallelism in fig. 2, caused by the finite width of the arms. A drawback of the bridge-shaped sample is that it is rather difficult to make, having to be cut out of the brittle semiconductor material with an ultrasonic tool. There is therefore a considerable risk of breakage, particularly when the arms are made narrow.

![Fig. 2. The bridge-type sample, which is provided with relatively large contact faces to reduce contact resistances. This form is of special importance in measurements at low temperatures.](image)

In the following we shall describe a method of performing resistivity and Hall-coefficient measurements on lamellae of arbitrary shape \(^2\). The lamella must not, however, contain any (geometrical) holes.

New method of measuring resistivity

We take a flat lamella, completely free of holes, and provide it with four small contacts, \(M\), \(N\), \(O\) and \(P\), at arbitrary places on the periphery (fig. 3). We apply a current \(i_{MN}\) to contact \(M\) and take it off at contact \(N\). We measure the potential difference \(V_p - V_o\) and define:

\[
R_{MN,OP} = \frac{V_P - V_O}{i_{MN}}.
\]

Analogously we define:

\[
R_{NO,PM} = \frac{V_M - V_P}{i_{NO}}.
\]

The new method of measurement is based on the theorem that between \(R_{MN,OP}\) and \(R_{NO,PM}\) there exists the simple relation:

\[
\exp\left(-\frac{\pi d}{\theta} R_{MN,OP}\right) + \exp\left(-\frac{\pi d}{\theta} R_{NO,PM}\right) = 1, \quad (1)
\]

where \(d\) is the thickness of the lamella and \(\theta\) the

\(^1\) See e.g. C. Kittel, Introduction to solid state physics, 2nd edition, Wiley, New York 1956, Chapter 13, p. 347 et seq.

resistivity of the material. If $d$ and the “resistances” $R_{MN,OP}$ and $R_{NO,PM}$ are known, then (1) yields an equation in which $\rho$ is the only unknown quantity.

$$\frac{d}{\rho} = \frac{R_{MN,OP} + R_{NO,PM}}{2\ln 2}$$

(3)

In this case a single measurement suffices.

In the general case it is not possible to express $\rho$ explicitly in known functions. The solution can, however, be written in the form

$$\rho = \frac{\pi d}{\ln 2} \frac{R_{MN,OP} + R_{NO,PM}}{2} f, \ldots \ldots$$

(4)

where $f$ is a factor which is a function only of the ratio $R_{MN,OP}/R_{NO,PM}$, as plotted in fig. 5. Thus, to determine $\rho$, we first calculate $R_{MN,OP}/R_{NO,PM}$, read from fig. 5 the corresponding value of $f$ and then find $\rho$ from (4).

Photographs of samples as used for the old and for the new method are shown in fig. 6.

The complete proof of the theorem underlying the measurement of $\rho$ is given in the paper quoted in footnote 2). The proof consists of two parts. First of all, relation (1) is developed for a special case, the case of a lamella in the form of an infinite half-plane, provided with four contacts at the periphery. It is then shown that the relation must also apply to a lamella of any shape. This is done by means of conformal mapping of the arbitrarily shaped plate on the infinite half-plane with the aid of complex functions.

We shall consider the first part of the proof in more detail, since it reveals the origin of the exponential functions in (1).

We first consider a lamella which extends to infinity in all directions. To a point $M$ we apply a current $2i$, which flows away from $M$ with radial symmetry into infinity. Let $d$ again be the thickness of the lamella and $\rho$ the resistivity. Then at a distance $r$ from $M$ the current density is

$$J = 2i/2\pi rd.$$

The field-strength $E$ is radially oriented and according to the generalized form of Ohm's law has the value:

$$E = \rho J = \rho i/\pi rd.$$
Fig. 6. Some samples of silicon used for resistivity and Hall-coefficient measurements. Samples a and b correspond respectively to figs. 1 and 2. Measurements on samples c and d are possible only by the new method. The incisions in sample d serve to reduce the error caused by the contacts not being infinitely small.

The potential difference between two points O and P lying on a straight line with M (fig. 7a) is:

\[ V_P - V_O = \int_0^0 E \, dr = \frac{q}{\sigma d} \int_0^0 \frac{d r}{r} = -\frac{q}{\sigma d} \ln \frac{a + b + c}{a + b} \]

Since no current flows in the direction perpendicular to the line through M, O and P, the result obtained remains valid if we omit the part of the lamella at one side of this line — yielding a half-plane — and if at the same time we halve the current (fig. 7b). Next we consider the case of c) in fig. 7, where a current \( i \) now flows out from a point N, that again lies on the same straight line with OP, viz. on the edge of the infinite half-plane. We now find:

\[ V_P - V_O = \frac{q}{\sigma d} \ln \frac{b + c}{b} \]

Superposition of the cases b) and c) in fig. 7 yields the case d), the current \( i \) being introduced at M and taken off at N. The value now assumed by \( V_P - V_O \) is found by adding together the two previous results. After dividing by \( i \) we then find:

\[ R_{MN,OP} = \frac{q}{\sigma d} \ln \frac{(a + b)(b + c)}{(a + b + c)b} \]

or

\[ \frac{a + b + c}{(a + b)(b + c)} = \exp \left( -\frac{\pi d}{q} R_{MN,OP} \right) \]

Similarly we find:

\[ \frac{a c}{(a + b)(b + c)} = \exp \left( -\frac{\pi d}{q} R_{NO,PM} \right) \]

Addition of the last two equations yields (1).

We shall now explain how formula (4) follows from (1). For simplification we put:

\[ \pi d R_{MN,OP} = x_1 \] \[ \pi d R_{NO,PM} = x_2 \] \[ x_1 + x_2 = \frac{\ln 2}{f} \]

Formula (1) can then be written:

\[ e^{-x_1} + e^{-x_2} = 1 \]

Next we write:

\[ x_1 = \frac{1}{b} \left( (x_1 + x_2) + (x_1 - x_2) \right) \]

\[ x_2 = \frac{1}{b} \left( (x_1 + x_2) - (x_1 - x_2) \right) \]

whereby (6) takes the form:

\[ e^{-\frac{x_1 + x_2}{2b}} (e^{-\frac{x_1 - x_2}{2b}} + e^{\frac{x_1 - x_2}{2b}}) = 1 \]

This is the same as:

\[ \frac{e^{-\frac{x_1 + x_2}{2b}}}{\cosh \frac{x_1 - x_2}{2b}} = \frac{1}{b} \]

The exponent of \( e \) in (7) is now written as \(-\frac{\ln 2}{f}\), i.e. we put:

\[ \frac{x_1 + x_2}{2b} = \ln 2 \]

Formula (7) then becomes:

\[ e^{\frac{\ln 2}{f}} \cos \left( \frac{1}{f} \left( \frac{1}{(x_1 + x_2) + (x_1 + x_2)} \frac{\ln 2}{f} \right) \right) = \frac{1}{b} \]

Fig. 7. Illustrating the derivation of formula (1).
This expression represents a relation between \( f \) and \( x_r/x_2 \), and hence also between \( f \) and \( R_{MN,OP}/R_{NO,PM} \) (see 5). The relation is shown graphically in fig. 5. By re-writing (8) to give \( q \) and substituting for \( x_1 \) and \( x_2 \) from (5), we find formula (4).

**Method of measuring the Hall coefficient**

The Hall coefficient, too, can be measured on an arbitrary lamella as in fig. 3. We then apply the current to one of the contacts, say \( M \), and take it off at the contact following the succeeding one, i.e. in our case at \( O \). We measure \( R_{MO,OP} \) after which we set up an uniform magnetic induction \( B \) at right angles to the surface of the lamella. This changes \( R_{MO,OP} \) by an amount \( \Delta R_{MO,OP} \). We shall now denote the Hall coefficient \( R_H \) and show that it is given by:

\[
R_H = \frac{d}{B} \Delta R_{MO,OP}, \quad \ldots \quad (9)
\]

provided that:

a) the contacts are sufficiently small,

b) the contacts are on the periphery,

c) the lamella is of uniform thickness and free of holes.

The validity of formula (9) depends on the distribution of current stream-lines not changing when the magnetic field is applied. With samples of the classical shape of figs. 1 and 2, where the current stream-lines are always parallel to the edges of the sample, there is evidently no change. From the properties of the vector field representing the current density it follows that the same also applies to lamellae of arbitrary shape, provided the above conditions are satisfied 3).

Under the magnetic induction \( B \), the charge carriers, with charge \( q \), are subjected to a force perpendicular to the stream-lines and perpendicular to the lines of magnetic induction. The magnitude of this force is \( F = qvB \), where \( v \) is the velocity of the charge carriers. Between \( v \), the concentration \( n \) of the charge carriers and the current density \( J \) there exists the relation \( v = J/nq \). Dividing the force exerted on the charge carriers by their charge \( q \), we see that the effect of the magnetic field is equivalent to an apparent electric field \( E_H \), the Hall electric field, for which we can write 4):

\[
E_H = \frac{1}{nq} J B .
\]

\( E_H \) is proportional to \( J \) and to \( B \); the proportionality constant \( (1/nq) \) is called the Hall coefficient \( R_H \).

Since \( q \) is known, one can calculate from \( R_H \) the concentration \( n \) of the charge carriers.

The fact that the current stream-lines are not affected by the magnetic field implies that after application of the magnetic field the electric field is no longer in the same direction as the current stream-lines, but has acquired a transverse component \( E_T \) which exactly compensates the apparent Hall electric field \( E_H \) (fig. 8). The change \( \Delta(V_P - V_N) \) in the potential difference between \( P \) and \( N \) is therefore given by integrating \( E_T \) from \( P \) over a path orthogonal to the current stream-lines to \( N' \) across the lamella (fig. 9), and hence along the periphery — i.e. along a stream-line — from \( N' \) to \( N \). The last portion of the path makes no contribution to the integral; hence

\[
\Delta(V_P - V_N) = \int_P^{N'} E_H \, ds = R_H B \int_P^{N'} J \, ds = R_H B \frac{\Delta R_{MO,OP}}{d},
\]

where \( d \) is again the thickness of the lamella. This expression leads directly to (9).

---

3) The proof of this statement is also indicated in the paper quoted under 5).

4) This formula is not entirely exact because, apart from their ordered motion with velocity \( v \), the electrons also move randomly owing to thermal agitation. More precise calculation shows, however, that the formula given here is a good approximation.
Estimation of errors

In the foregoing we have assumed the contacts to be “sufficiently” small and to be situated on the periphery. To gain an idea of the error made in the calculations when these conditions are not exactly satisfied, we have worked out the error for three cases. For simplicity we consider a circular disc of diameter $D$ with the contacts mutually 90° apart. We assume further that only one of the contacts is not ideal. The three cases are represented in the adjoining table, together with the formulae for the relative errors in the resistivity and the Hall coefficient. The cases are:

a) One of the contacts has a length $l$ along the periphery.

b) One of the contacts has a length $l$ perpendicular to the periphery.

c) One of the contacts, although a point, is situated at a distance $l$ from the periphery.

In practice, none of the contacts will be ideal. To the first approximation the total error is then equal to the sum of the errors per contact.

The value of the method described here lies in the fact that, in many cases, the material under investigation is already available in the form of small lamellae (e.g. thin discs sawn from a crystal rod); these samples now need no further preparation and can therefore be used for other purposes after the measurement.

If very small contacts are undesirable, having regard to contact resistances in measurements at low temperature, use can be made of “clover-leaf” samples (see fig. 6d), the incisions in which substantially reduce the error due to the finite dimensions of the contacts. The clover-leaf sample thus replaces the bridge-type sample (fig. 6b) which is used for the same purpose in the classical method. The clover-leaf sample is easier to make than the bridge-type sample and is also less susceptible to breakage.

L. J. van der PAUW.
